

Do adults behave like children when under pressure?

Samuel Giacomelli (S.Giacomelli@student.rug.nl)

Abstract

Do adults behave like children when under pressure? If children perform differently because they have more limited cognitive resources, like working memory, if you load adults working memory can you then get them to show childlike behavior/interpretations?

Introduction

Atypical universal quantification

In the past year the tendency for children to give atypical interpretation to sentences containing universal quantifiers (e.g. *each*), has been studied deeply. In the first works they were just claimed to exhibit atypical universal quantification (Piaget et al. (1964)), and later studies proved that children attribute to the extra objects, or extra subjects contained in the picture the cause of their atypical answer (Philip (1994)). In that study when children, from three to five years old, were presented a question like *"Is every man wearing a hat?"* along with a picture showing some men wearing a hat and an extra hat, they would answer *"No"* pointing to the extra object (i.e. the hat) as the reason of their answer. This kind of interpretation takes the name of *SYMMETRICAL RESPONSE* (SR), because of the fact that the extra object ruins the situation of symmetry depicted in the picture. On the other hand, adults' typical response is called *LOGICAL READING* (LG), since adults' answer to the former question would have been *"Yes"* and it would have been the output of a logical analysis of the picture given the sentence. A recent study by Minai et al. (2012) proved that children are capable of reaching both of the kind of responses and that what lets them give a LG response is the level of cognitive development, which they tested through a Dimensional Change Card Sorting task. The question that came on our mind after knowing about their results was *"If children give SR responses do to their limited cognitive capabilities, does it also work with adults that for some reason are under pressure or have they working memory particularly loaded?"*.

Present Study

Truth Value Judgment (TVJ) task (Crain and Thornton (2000)) Use both extra object and extra subject picture.

For this experiment we will use materials very similar to the one used in Minai et al. (2012), with the difference that in addition to under exhaustive scenes, in which objects are more than subjects, we will provide also over exhaustive ones (i.e. images in which subjects are greater in number than objects). Another important change to the original images will be done and it will consist in moving the extra objects, or the extra subjects, respectively, in all the four lattices in which the

image is divided. This hasn't been done in the work of Minai et al. (2012) and it could have led to a lack of processing of the image presented.

Investigate on adult tendency to commit universal quantification when their cognitive resources are limited. *The present study aims at examining this hypothesis.*

Symmetrical response (SR) and Logical reading (LG) in children and adults do to low level of *COGNITIVE CONTROL*. Multiple numbers (≥ 6) of extra objects almost perfect LG (Sugisaki and Isobe (2001)).

Desired number of extra object should be the one that is capable to elicit both LG and SR responses.

Ability to flexibly switch perspective, children are inflexible (Piaget (1954)).

Children between 4 and 5 yo as in (Minai et al. (2012)). Because they're able to provide both SR and LG responses

One group of adults 20-30.

Question-answer Requirement -> sentences are interpreted as answers to particular questions. Maybe under pressure the participant tend to find easier question, leading to commit errors and universal quantification.

Method

Participants

Our participants will be divided in two groups. The first one will be the *CONTROL* and is going to be composed by around 40 english acquiring children between 4 and 5 years old, while the *TARGET* group will consist of at least 40 english native speakers adults between 20-40¹ years old. Both the *CONTROL* and the *TARGET* group will be composed in equal parts by males and females in order to provide more consistent and reliable data for the analysis. The participants of the *CONTROL* group will have to complete just the *TVJ* task to determine the baseline of the childlike behavior, while the one composing the *TARGET* group will have to complete both the *SDR* and the *TVJ* task simultaneously.

Procedure

TVJ Participants will be placed in front of a screen reporting in the beginning just a button with the label *START* in the centre-bottom of it. After having clicked on this button, a picture will be presented in the top centre of the display followed after 2500ms by a spoken sentence. In the exact moment in which the subject starts hearing the sentence he has to move the mouse toward the answer they think it is correct, in our

¹Subjects in this age span should have completely developed their linguistic and cognitive skills

case the possible answers are "YES/NO" and are presented in two boxes on the left and on the right of the picture (at the exact same distance from the centre and the start button to let us collect consistent information about the trajectories). If the subject is too slow in the beginning he/she will be asked to start moving the mouse earlier. In order to display the following picture and so the following step of the task the subject has to click on the start button (which will appear in the same position as before) again. Knowing that this kind of procedure might be demanding for the children we take in account the possibility for them to take a break during the execution of the experiment (exactly in the middle of it, before the beginning of the combined *TVJ-SDR* task), while adults won't be able to take a break, because at that moment they will be also in the middle of their *SDR* task.

SDR Both children and adults (i.e. *CONTROL* and *TARGET*) will be asked to go through a Single Digit Recall (*SDR*) task while performing the *TVJ* one. This task consists in remembering a sequence of variable length, for children it will be of three numbers, while for adults it will be made of six numbers, and, at the end of the *TVJ* task, recalling the sequence in the exact order in which it was presented. For both adults and children the single digits will be displayed on the screen for one second between the steps of the *TVJ* task, but there will be some difference in the presentation patterns between adults and children that we are going to explain below.

Adults When adults press the start button for the first time a digit will appear on the screen and will stay there for 1 second. After this period of time the first part of the *TVJ* task will begin and after three steps this procedure will be repeated and another digit will be shown on the screen. In this way, they will have to remember a total of six digits which in accord of the findings of Taub (1972) is a little bit below the maximum number of digits that an average 30yo adult can remember. The way chosen to propose the *SDR* task is specifically thought to progressively increase the load on the working memory of the subjects, letting them with less available cognitive resources to process the response to the *TVJ* task's questions and trying to elicit in them a childlike behavior.

Children The *SDR* task for children doesn't start with the first step of the *TVJ* task, but after the break in the middle of it, because children's working memory has a more limited capacity and they won't be able to remember the six numbers. In this way, at the end of the experiment, they will have to remember just three digits.

Materials

Sentences As this study is partially inspired by the work of Minai et al. (2012), the stimuli used for the *TVJ* task are the english translations of the ones presented in their paper, with the only difference that is necessary to add a *filler item* in order to have an even number of stimuli, which are necessary to divide the task in two blocks. The stimuli sentences are therefore 18 and are divided in three groups, respectively: 8

target sentences, 8 filler sentences and 2 warm-up sentences. Below we report an example of a target sentence (1). All the sentences will be spoken by both a male and a female english native speaker and recorded in order to be presented to the participants in form of an audio track.

- (1) Every turtle is holding an umbrella.

Differently from Minai et al. (2012) we associated to the target sentences both the under and over-exhaustive scenes. This means that we have 2 showable stimuli for each sentence. Participants are presented in the same proportion under and over-exhaustive ones, respectively four for each type, but they are never presented the same sentence with the two different images that describe it, in order to avoid priming. In addition another change will be done on the images used in the above cited study that consist in moving the extra object in different positions of the image. Since in the original paper they were always in the bottom right lattice, we think that this disposition made the children focus their attention always on a minimal part of the image and in particular on the extra objects. Below (Figure 1) we report an example of the images that will be used in our research.

Figure 1: Example of images used in the experiment. Picture a. shows the under exhaustive case, while picture b. the over exhaustive one

Digits' sequences

The stimulus sets consisted in sequences of six digits each (one every three steps of the *TVJ* task), each of them from 1 to 9 without repetition within the same sequence. Furthermore, according to the work of Taub (1972) one more restriction will be applied on the sequences, which consists in not presenting adjacent pairs of digits in the correct counting order (neither increasing or decreasing).

Results

Data Analysis

Since every subject will perform a *TVJ* task and the technology used to design it concerns the use of the mouse tracker, we will be able to collect not only the final answer of the subjects but also some information about the process of decision making. We will analyse the percentage of *SR* and *LG* responses in children and adults to see whether the adults behave in the same way that children do while performing both the *TVJ* and the *SDR* tasks. To analyse the data we will divide the one collected from both adults' and children's *TVJ* task in two blocks, one containing the answers given in the first half of the task (when the working memory load was still low for adults and absent for children), and the other one containing the answers given in the second half (with the maximum cognitive load for both of the groups). In this way we will be able to see whether there is a relation between the increasing cognitive load and the tendency to give childlike responses, but also if the responses given by children are influenced too by the higher cognitive load. This approach will lead in an ANOVA analysis of the average *LG* and accordingly *SR* responses with a (2) group x (2) cognitive-load design, where both group (*CONTROL* vs *TARGET*) and cognitive-load (*LOW* vs *HIGH*) are between subjects factors. Continuous data about the decision making process that starts with the presentation of the audio stimuli will be analyzed in order to see whether there is: (a) a commitment toward the wrong answer to the question (and so toward the wrong interpretation of the scene) when the workload is *HIGH* in adults, (b) a similarity in the trajectories of the decision making process of adults with a *HIGH* working memory load and children with a *LOW* one, (c) a similarity in the values relative to the Maximum Deviation (MD) from the ideal trajectory and the value of the Area Under the Curve (AUC) between adults with a high working memory load and children and (d) an increment in the Reaction Times in adults with a *HIGH* cognitive load meaning that they need more time to choose the right answer to the question.

Expected Results

The results that we expect from the above described analysis are multiple. First of all, when it comes to the analysis of the average of *LG* responses between the two groups and the two different levels of cognitive load, we expect to see a higher percentage of *SR* responses in both adults and children in a situation of *HIGH* cognitive load. When looking at

the differences between the two groups we expect to notice that the percentages of *LG* responses for children in a condition of *LOW* cognitive load is very similar to the one of adults with *HIGH* cognitive load. If that's the case we will be able to prove our initial hypothesis on the basis of the data acquired thanks to this experiment. Second of all, when it comes to the analysis of the mouse tracker data, we expect to see a similarity in the trajectories of children with a *LOW* cognitive load and adults with a *HIGH* one, depicting that the decision making process of subjects belonging to the two different groups are very similar under this condition. Furthermore, we expect to see a commitment toward the wrong answer when analyzing mouse tracking data about adults in a condition of *HIGH* cognitive workload. Maybe the cognitive load won't be enough to make them go for the wrong answer but if our hypothesis is true we will also be able to see that adults are more on the fence and need further reasoning, so more time, to choose the right answer.

Discussion

In this study we investigated the role of the working memory in the interpretation of the universal quantifier *every*. We wanted to prove that with a limited cognitive capacity adults tend to behave like children (i.e. provide a *SR*) when a sentence like (1) is presented combined to one of the two images in Figure 1. If our results will prove this childlike behavior it will mean that we found a cue that linguistic capabilities are strongly connected and more interestingly strongly dependent on cognitive capabilities. It will also provide some support to the thought that the linguistic development in children directly depends on their cognitive development. It will open the doors for lots of possible researches about the relation between the two, for example one could try to answer the question "*Are people slower in disambiguating ambiguous sentences when they are in the situation of a high cognitive load?*", but at the same time it may answer question proposed from the opposite point of view, such as "*Does the process of disambiguation of ambiguous sentences reduce our free working memory? And how much?*".
